Spring 2016
Outline

1. Eigenvalue Problems
   - Introduction
   - Unitary Diagonalization

2. Eigenvalues...
   - Schur Factorization
   - Algorithms
We review the language and properties associated with eigenvalue problems, and describe three example of matrix factorizations which reveal the eigenvalues of a matrix $A$:

- **The diagonalization** $A = XX^{-1} \iff X^{-1}AX = \Lambda$, where $\Lambda = \text{diag}(\lambda_1, \lambda_2, \ldots, \lambda_n)$, and the columns of $X$ contains the eigenvectors of $A$.

- **The unitary diagonalization** $A = Q\Lambda Q^* \iff Q^*AQ = \Lambda$.

- **The unitary triangularization** (a.k.a. Schur factorization) $A = QTQ^* \iff Q^*AQ = T$, where $T$ is upper triangular, and the eigenvalues of $A$ appear on the diagonal of $T$.

We discuss under what circumstances each of these factorizations exist.
Eigenvalue Problems — (4/27)

Let \(A \in \mathbb{C}^{m \times m}\) be a square matrix. A non-zero vector \(\bar{x} \in \mathbb{C}^m\) is an eigenvector of \(A\), and \(\lambda\) is the corresponding eigenvalue is

\[
A\bar{x} = \lambda\bar{x}.
\]

The set of all eigenvalues of a matrix \(A\) is the spectrum of \(A\), commonly denoted by \(\lambda(A)\), or \(\Lambda(A)\).

The usefulness of eigenvalues and eigenvectors

**Algorithmic**

Eigenvalue analysis can simplify solutions by reducing a coupled system to a collection of scalar problems.

**Physical**

Eigenvalue analysis can give insight to the behavior of evolving systems governed by linear equations, e.g. the study of resonance and stability of physical systems.
The eigenvalue decomposition of a square matrix is the factorization

\[ A = X\Lambda X^{-1}, \]

where \( X \) is non-singular and \( \Lambda \) diagonal. To make the connection between eigenvalues and eigenvectors clear, this decomposition can be rewritten

\[ AX = X\Lambda. \]

\[
\begin{bmatrix}
A \\
\bar{x}_1 & \bar{x}_2 & \cdots & \bar{x}_m
\end{bmatrix}
= 
\begin{bmatrix}
\bar{x}_1 & \bar{x}_2 & \cdots & \bar{x}_m
\end{bmatrix}
\begin{bmatrix}
\lambda_1 & \lambda_2 & \cdots & \\
& & & \lambda_m
\end{bmatrix}
\]

Showing that

\[ A\bar{x}_j = \lambda_j \bar{x}_j. \]
The eigenvalue decomposition can be viewed as a change of basis to “eigenvector coordinates.”

In solving the problem $A\bar{x} = \bar{b}$, with $A = XX^{-1}$, we have

$$\Lambda(X^{-1}\bar{x}) = X^{-1}\bar{b}$$

To compute $A\bar{x}$, we expand $\bar{x}$ in the basis of columns $X$, apply $\Lambda$, and interpret the result as a vector of coefficients of a linear combination of the columns of $X$...
Eigenvalues: Geometric Multiplicity

The set of eigenvectors corresponding to a single eigenvalue, together with the zero-vector, form a subspace $S$ of $\mathbb{C}^m$ known as an eigenspace.

If $\lambda \in \Lambda(A)$, we denote the corresponding eigenspace by $E_\lambda$.

An eigenspace $E_\lambda$ is an example of an invariant subspace of $A$, i.e. $AE_\lambda \subseteq E_\lambda$.

The dimension of $E_\lambda$ can be interpreted as the maximum number of linearly independent eigenvectors that can be found corresponding to the eigenvalue $\lambda$. This is the geometric multiplicity of $\lambda$.

We note that

$$\text{null}(A - \lambda I_{m \times m}) = E_\lambda.$$
The characteristic polynomial of \( A \in \mathbb{C}^{m \times m} \), is the polynomial of degree \( m \) defined by

\[
p_A(z) = \det(zI_{m \times m} - A).
\]

The following theorem is well-known

**Theorem**

\( \lambda \) is an eigenvalue of \( A \) if and only if \( p_A(\lambda) = 0 \).

We note that even if \( A \) is real, the eigenvalues may be complex. Further, we note that from previous discussion (recall Wilkinson’s example in lecture #9) on the ill-conditioning of the root-finding problem, looking for roots to the characteristic polynomial is not the way to identify eigenvalues!
By the fundamental theorem of algebra, \( p_A(z) \) can be factored

\[
p_A(z) = (z - \lambda_1)^{m_1} (z - \lambda_2)^{m_2} \cdots (z - \lambda_r)^{m_r},
\]

where

\[
\sum_{k=1}^{r} m_k = m.
\]

The integers \( m_k \geq 1 \) indicate the algebraic multiplicity of the eigenvalue \( \lambda_k \).

The following is true

\[
\text{Algebraic multiplicity}(\lambda_k) \geq \text{Geometric multiplicity}(\lambda_k)
\]

This result comes from a discussion of similarity transformations.
Similiarity Transformations

If $X \in \mathbb{C}^{m \times m}$ is non-singular, then the map

$$A \rightarrow X^{-1}AX,$$

is called a similarity transformation of $A$. Two matrices $A$ and $B$ are similar if there exists a non-singular $X \in \mathbb{C}^{m \times m}$ such that $B = X^{-1}AX$.

We care about similarity transformations because:

**Theorem**

*If $X \in \mathbb{C}^{m \times m}$ is non-singular, then $A$ and $X^{-1}AX$ have the same characteristic polynomial, eigenvalues, and algebraic and geometric multiplicities.*
The proof of the theorem is very straight-forward:

\[ p_{X^{-1}AX}(z) = \det(zI - X^{-1}AX) = \det(X^{-1}(zI - A)X) = \det(X^{-1}) \det(zI - A) \det(X) = \det(zI - A) = p_A(z). \]

Since \( p_{X^{-1}AX}(z) = p_A(z) \) the agreement on eigenvalues, and algebraic multiplicities follow. The agreement of geometric multipliers follows from the fact that if \( E_\lambda \) is an eigenspace for \( A \), then \( X^{-1}E_\lambda \) is an eigenspace for \( X^{-1}AX \), and conversely. \( \square \)

With this result in our back-pocket we can show

Theorem

*The algebraic multiplicity of an eigenvalue \( \lambda \) is at least as great as its geometric multiplicity.*
Proof: Algebraic multiplicity ≥ Geometric multiplicity

Let \( n \) be the geometric multiplicity of \( \lambda \) for the matrix \( A \). Form an \( m \times n \) matrix \( \hat{V} \) whose \( n \) columns constitute an orthonormal basis of \( E_\lambda \). Let \( V \) be the square unitary matrix whose first \( n \) columns are given by \( \hat{V} \), and define \( B \) by

\[
B = V^* A V = \begin{bmatrix} \lambda I_{n \times n} & C \\ 0 & D \end{bmatrix}, \quad C \in \mathbb{C}^{n \times (m-n)}, \quad D \in \mathbb{C}^{(m-n) \times (m-n)}.
\]

By the definition of the determinant,

\[
\det(zI_{m \times m} - B) = \det((z - \lambda)I_{n \times n}) \det(zI_{(m-n) \times (m-n)} - D) \\
= (z - \lambda)^n \det(zI_{(m-n) \times (m-n)} - D).
\]

Hence, the algebraic multiplicity of \( \lambda \) as an eigenvalue of \( B \) is at least \( n \). Since similarity transformations preserve multiplicities, the same is true for \( A \). \( \square \)
When **Algebraic multiplicity** > **Geometric multiplicity**, the matrix is not diagonalizable. Consider

\[
A = \begin{bmatrix}
  2 & & \\
  & 2 & \\
  & & 2
\end{bmatrix}, \quad B = \begin{bmatrix}
  2 & 1 & \\
  & 2 & 1 \\
  & & 2
\end{bmatrix}.
\]

Both \(A\) and \(B\) have \(\lambda = 2\) with **algebraic multiplicity** 3. For \(A\) we can choose 3 independent eigenvectors, but for \(B\) there is only one independent eigenvector

\[
\bar{x}_{A_1} = \begin{bmatrix}
  1 \\
  0 \\
  0
\end{bmatrix}, \quad \bar{x}_{A_2} = \begin{bmatrix}
  0 \\
  1 \\
  0
\end{bmatrix}, \quad \bar{x}_{A_3} = \begin{bmatrix}
  0 \\
  0 \\
  1
\end{bmatrix}, \quad \bar{x}_{B_1} = \begin{bmatrix}
  1 \\
  0 \\
  0
\end{bmatrix}
\]

**Geometric multiplicities** of \(\lambda = 2\) are 3 (for \(A\)) and 1 (for \(B\)).
An eigenvalue whose algebraic multiplicity exceeds its geometric multiplicity, is a **defective eigenvalue**. A matrix that has one or more defective eigenvalues is a **defective matrix**.

A non-defective matrix is **diagonalizable** —

**Theorem**

An $m \times m$ matrix $A$ is non-defective if and only if it has an eigenvalue decomposition $A = X\Lambda X^{-1}$.

This result quantifies for what matrices the diagonalization is (theoretically) computable. — The matrix $X$ may be highly ill-conditioned, which may prevent us from numerically performing the diagonalization.
In rare circumstances, we come across a matrix $A \in \mathbb{C}^{m \times m}$ whose $m$ eigenvectors not only are linearly independent, but can be chosen to be orthogonal.

In this case $A$ is **unitarily diagonalizable**, *i.e.* there exists a unitary matrix $Q$ such that

$$A = Q \Lambda Q^*.$$

Since $\|Q\|_2 = 1$, there is no ill-conditioning to worry about.

**What kind of matrices are unitarily diagonalizable??**
Unitarily Diagonalizable Matrices

Theorem

A Hermitian matrix is unitarily diagonalizable, and its eigenvalues are real.

Other examples of unitarily diagonalizable matrices include

- **Skew-Hermitian** matrices, $S^* = -S$.
- **Unitary matrices**, $U^* = U^{-1}$, $U^* U = I$.
- **Circulant matrices**, $C$, whose rows are composed of cyclically shifted versions of a length-$n$ list $l$.
- Any of the above **plus** a multiple of the identity.

These types of matrices are all **normal**, i.e. $M^* M = MM^*$.

Theorem

A matrix is unitarily diagonalizable if and only if it is normal.
If we are interested in \textbf{numerically computing} the \textit{eigenvalues} only, then the Schur factorization is the most useful approach.

The \textbf{Schur factorization} of a matrix $A$ is a unitary factorization

$$A = QTQ^*, \quad \text{where } Q \text{ is unitary, and } T \text{ is upper triangular. Since this is a similarity transform, the eigenvalues of } A \text{ must appear on the diagonal of } T.$$
The following theorem indicates why this is a useful approach —

Theorem

*Every square matrix $A$ has a Schur factorization.*

Hence it should be possible to compute the eigenvalues for any matrix, without having to worry about ill-conditioning in the $X$ (here $Q$) matrix which defines the similarity transformation.
The Schur Factorization: Existence Proof

The proof is by induction. The base case $m = 1$ is trivially true.

Let $m \geq 2$ [the inductive hypothesis says that there exists a Schur factorization of all $(m - 1) \times (m - 1)$ matrices], and let $(\lambda, \bar{x})$ be any eigenvalue-eigenvector pair of $A$. Let $\bar{u}_1 = \bar{x}/\|\bar{x}\|_2$ be the first column of a unitary matrix $U$. Then by construction,

$$U^*AU = \begin{bmatrix} \lambda & B \\ 0 & C \end{bmatrix},$$

where $B \in \mathbb{C}^{1 \times (m-1)}$, and $C \in \mathbb{C}^{(m-1) \times (m-1)}$.

Now, by the induction hypothesis $C = VT\bar{V}^*$ for some unitary $V \in \mathbb{C}^{(m-1) \times (m-1)}$, and upper-triangular $T \in \mathbb{C}^{(m-1) \times (m-1)}$. Therefore we can define

$$Q = U \begin{bmatrix} 1 \\ V \end{bmatrix}.$$
$Q$ is unitary, and

$$Q^*AQ = \begin{bmatrix} 1 & \mathbb{V}^* \end{bmatrix} \begin{bmatrix} U^*A & U^*B \\ V^*C & V^*D \end{bmatrix} \begin{bmatrix} 1 \\ \mathbb{V} \end{bmatrix} = \begin{bmatrix} \lambda & BV \\ 0 & T \end{bmatrix}$$

which is the Schur factorization we want. □
Eigenvalue-Revealing Factorizations

We have described three eigenvalue-revealing factorizations

<table>
<thead>
<tr>
<th>Type</th>
<th>Form</th>
<th>Restrictions on $A$</th>
<th>Vectors</th>
</tr>
</thead>
<tbody>
<tr>
<td>Diagonalization</td>
<td>$A = X\Lambda X^{-1}$</td>
<td>Non-defective</td>
<td>✓</td>
</tr>
<tr>
<td>Unitary Diagonalization</td>
<td>$A = Q\Lambda Q^*$</td>
<td>Normal, $A^* A = AA^*$</td>
<td>✓</td>
</tr>
<tr>
<td>Schur Triangularization</td>
<td>$A = QTQ^*$</td>
<td>None</td>
<td>—</td>
</tr>
</tbody>
</table>

Note that the diagonalizations also give the eigenvectors, whereas the eigenvector information is lost in the Schur triangularization.

The factorizations based on unitary transformations tend to lead to algorithms that are numerically stable.

If $A$ is normal, then the Schur form comes out diagonal, and if $A$ is Hermitian we can take advantage of the symmetry in order to save (approximately) half the work.
Even though eigenvalues and eigenvectors have straightforward definitions and clean characterizations, the best ways to compute them are not obvious.

Some of the most “obvious” ways of approaching the problem — e.g. by extracting the roots of the characteristic polynomial — are not stable.

The **power iteration** which generates the sequence

\[
\frac{\tilde{x}}{\|\tilde{x}\|}, \frac{A\tilde{x}}{\|A\tilde{x}\|}, \frac{A^2\tilde{x}}{\|A^2\tilde{x}\|}, \frac{A^3\tilde{x}}{\|A^3\tilde{x}\|}, \ldots
\]

will, under some weak conditions, converge to the eigenvector corresponding to the largest (in absolute value) eigenvalue. This approach is **slow** in general — and it only gives one eigenvector.
General purpose eigenvalue algorithms are based on computing eigenvalue-revealing factorizations of $A$.

Depending on the properties of the matrix $A$, we can base our algorithms on diagonalization, unitary diagonalization, or unitary triangularization.

Clearly, we are going to pull out the tools we have already developed for generating algorithms that “put zeros into matrices.”

Although, the flavor is related, eigenvalue computations are distinctly different (and fundamentally more difficult) than solutions of linear systems, or least squares problems.
We have seen that we can cast the eigenvalue problem as a root-finding problem (subject to potentially catastrophic ill-conditioning).

Conversely, any polynomial root-finding problem can be stated as an eigenvalue problem, e.g. given the polynomial

\[ p(z) = z^m + a_{m-1}z^{m-1} + \cdots + a_1z + a_0, \]

we can write \( p(z) = (-1)^m \cdot \det(A - zI), \) where

\[
A - zI = \begin{bmatrix}
-z & -a_0 & & \\
1 & -z & & \\
 & 1 & -z & \\
 & & \ddots & \ddots \\
 & & & 1 & -z & -a_{m-2} \\
 & & & & 1 & -(z + a_{m-1})
\end{bmatrix}.
\]
Therefore the roots of $p(z)$ are the eigenvalues of the matrix

$$A = \begin{bmatrix} 0 & 0 & \cdots & -a_0 \\ 1 & 0 & \cdots & -a_1 \\ 1 & 1 & \cdots & -a_2 \\ \vdots & \vdots & \ddots & \vdots \\ \vdots & \vdots & & \vdots \\ \vdots & \vdots & & 0 \\ 1 & \cdots & & -a_{m-2} \\ 1 & \cdots & & -a_{m-1} \end{bmatrix}$$

We are in quite a predicament! — It is well known that there is no formula for expressing the roots of an arbitrary polynomial given its coefficients.
In 1824 Niels Henrik Abel proved the following theorem:

**Theorem**

For any \( m \geq 5 \), there is a polynomial \( p(z) \) of degree \( m \) with rational coefficients that has a real root \( p(r) = 0 \) with the property that \( r \) cannot be written using any expression involving rational numbers, addition, subtraction, multiplication, division, and \( k \)th roots.

This theorem seems to spell out a lot of gloom-and-doom: even in exact arithmetic, there can be no computer program that produces the exact roots of an arbitrary polynomial in a finite number of steps.
A Different Angle of Attack

The preceding discussion does not mean that we cannot generate a good eigenvalue solver. It does, however, indicate that we have to think “outside the box” (where the box is our present toolbox of algorithms).

Gaussian elimination and Householder reflections would solve linear systems of equations exactly in a finite number of steps if they could be implemented in exact arithmetic. However

Fact

Any eigenvalue solver must be iterative.

We are going to generate sequences of numbers converging rapidly toward the eigenvalues. — The need for iterations may seem discouraging; however, in most cases we can define schemes that converge very rapidly — doubling or tripling the number of digits of accuracy in each iteration.
