## Outline

(1) Nonlinear Least Squares Problems

- Introduction
- Example / Background
(2) Special Case: Linear Least Squares
- Quick Review / Crash Course

In least squares problems, the objective function $f$ has a special form

$$
f(\overline{\mathbf{x}})=\frac{1}{2} \sum_{j=1}^{m} r_{j}(\overline{\mathbf{x}})^{2}, \quad \overline{\mathbf{x}} \in \mathbb{R}^{n}
$$

we refer to each $r_{j}$ as a residual. We assume, for now, that $m \geq n$ so that we have more residuals than dimensions (independent variables). [OVER-DETERMINEd]
The least squares formulation is useful for fitting model parameters to data and has applications in a wide range of fields: chemistry, physics, engineering, finance, economics, etc.

It answers the question "What model (in a certain class) best fits the observed data?"

The least-squares-objective has a special form, which makes it easier to solve than general non-linear minimization problems:
We assemble the residual vector

$$
\overline{\mathbf{r}}(\overline{\mathbf{x}})=\left[r_{1}(\overline{\mathbf{x}}), r_{2}(\overline{\mathbf{x}}), \ldots, r_{m}(\overline{\mathbf{x}})\right]^{T}
$$

Hence, the objective can be written as

$$
f(\overline{\mathbf{x}})=\frac{1}{2} \overline{\mathbf{r}}(\overline{\mathbf{x}})^{T} \overline{\mathbf{r}}(\overline{\mathbf{x}})=\frac{1}{2}\|\overline{\mathbf{r}}(\overline{\mathbf{x}})\|_{2}^{2} .
$$

We are going to express the derivatives of $f(\overline{\mathbf{x}})$ in terms of the Jacobian of $\overline{\mathbf{r}}(\overline{\mathbf{x}})$, which is the $m \times n$ matrix of first partial derivatives defined by

$$
J(\overline{\mathbf{x}})=\left[\frac{\partial r_{j}(\overline{\mathbf{x}})}{\partial x_{i}}\right]_{\substack{j=1,2, \ldots, m \\ i=1,2, \ldots, n}}
$$

With the Jacobian notation we can write

$$
\begin{aligned}
\nabla f(\overline{\mathbf{x}}) & =\sum_{j=1}^{m} r_{j}(\overline{\mathbf{x}}) \nabla r_{j}(\overline{\mathrm{x}})=J(\overline{\mathrm{x}})^{T} \overline{\mathrm{r}}(\overline{\mathrm{x}}) \\
\nabla^{2} f(\overline{\mathrm{x}}) & =\sum_{j=1}^{m} \nabla r_{j}(\overline{\mathrm{x}}) \nabla r_{j}(\overline{\mathrm{x}})^{T}+\sum_{j=1}^{m} r_{j}(\overline{\mathrm{x}}) \nabla^{2} r_{j}(\overline{\mathrm{x}}) \\
& =J(\overline{\mathrm{x}})^{T} J(\overline{\mathbf{x}})+\sum_{j=1}^{m} r_{j}(\overline{\mathbf{x}}) \nabla^{2} r_{j}(\overline{\mathrm{x}})
\end{aligned}
$$

Usually $J(\overline{\mathbf{x}})$ can be computed explicitly without too much work. This gives us a way to get the gradient $\nabla f(\overline{\mathbf{x}})$. Further, this gives us the first "half" of the Hessian $\nabla^{2} f(\overline{\mathbf{x}})$ for "free," i.e. without computing any second derivatives.

In many applications, the second part of the Hessian is small. When this happens we can exploit this by approximating $\nabla^{2} f(\overline{\mathbf{x}}) \approx J(\overline{\mathbf{x}})^{T} J(\overline{\mathbf{x}})$ so that we have a good approximation of the Hessian, without computing any second derivatives!!!

All our previously defined minimization algorithms can be applied to the least squares problem

$$
\min _{\overline{\mathbf{x}} \in \mathbb{R}^{n}} f(\overline{\mathbf{x}})=\frac{1}{2} \min _{\overline{\mathbf{x}} \in \mathbb{R}^{n}}\|\overline{\mathbf{r}}(\overline{\mathbf{x}})\|_{2}^{2}
$$

In essence, we just take our old algorithms, and change them to exploit the special structure of the gradient and Hessian.

Prior to hammering out all the gory details, lets take a closer look at the origins of nonlinear least-squares problems.

## Least Squares Fitting: Background / Example \#1

Example: We study the effect of a certain medication on a patient. Blood is drawn at certain times $\left\{t_{j}\right\}$ after the patient takes a dose - the concentration of the medication in the patient's blood-stream $\left\{y_{j}\right\}$ is measured.

We think that the following model is a good description of the process

$$
\Phi(\overline{\mathbf{x}} ; \mathbf{t})=\mathbf{x}_{1}+\mathbf{x}_{2} \mathbf{t}+\mathbf{e}^{-\mathrm{x}_{3} \mathrm{t}}
$$

Here, $x_{1}, x_{2}$, and $x_{3}$ are the parameters of the model (to be determined), and $t$ indicates time.

We seek to determine the parameters so that the discrepancy between the concentrations predicted by the model $\left\{\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right\}$, and the observed concentrations $\left\{y_{j}\right\}$ are minimized in the least squares sense.

## Least Squares Fitting: Background / Example \#1

Figure: An illustration of the discrepancy between the model (solid blue line), and the measurements (red dots). The size of the deviation is indicated by the solid red vertical lines.

## Least Squares Fitting: Background / Example \#3

The least-squares error is measured by the objective

$$
f(\overline{\mathbf{x}})=\frac{1}{2} \sum_{j=1}^{m}\left[y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right]^{2}
$$

Note that at this point $\left\{t_{j}, y_{j},\right\}_{j=1}^{m}$ are known, and the values $\overline{\mathbf{x}}$ are unknown.

By solving the least-squares-problem

$$
\overline{\mathbf{x}}^{*}=\underset{\overline{\mathbf{x}} \in \mathbb{R}^{n}}{\arg \min } f(\overline{\mathbf{x}})
$$

we find the model

$$
\boldsymbol{\Phi}\left(\overline{\mathbf{x}}^{*} ; \mathbf{t}_{\mathbf{j}}\right)=\mathbf{x}_{\mathbf{1}}^{*}+\mathbf{x}_{2}^{*} \mathbf{t}+\mathbf{e}^{-\mathrm{x}_{3}^{*} \mathbf{t}}
$$

which best fits the measurements.

## Least Squares Fitting: Background / Example \#2

Figure: Neonatal cardiocyte.
Possible model for $\mathrm{Ca}^{2+}$ ion concentration in a cardiocyte during the relaxation phase:

$$
c(t)=A e^{-\alpha t}+B e^{-\beta t}
$$

## Least Squares Fitting: Background

The previous example ( $\# 1$ ) is an instance of what is known as a fixed-regressor model in statistics. It assumes that the times $\left\{t_{j}\right\}$ at which we draw blood are known to high accuracy, while the observations $\left\{y_{j}\right\}$ contain "random" errors due to equipment limitations and/or human error.

The least-squares objective is by far not the only way to measuring the discrepancy, we could use

$$
\sum_{j=1}^{m}\left[y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right]^{16}, \text { or } \sum_{j=1}^{m}\left|y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right|, \text { or } \max _{j=1,2, \ldots, m}\left|y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right|
$$

However, the sum-of-squares measure is
(i) easier to work with
(ii) (usually) the correct choice for statistical reasons...

## Least Squares Fitting: Background — Statistics (Handwaving) 1 of 3

Close your eyes if you are a real statistician!
Let $\epsilon_{j}$ denote the discrepancy at measurement $\# j$, i.e.

$$
\epsilon_{j}=y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)
$$

In many cases it is reasonable to assume that the $\epsilon_{j}$ are independent and identically distributed ("iid"), with a variance $\sigma^{2}$ and probability density function $g_{\sigma}(\cdot)$.

This assumption will often be true, e.g. when the model accurately reflects the actual process, and when the errors do not contain a "systematic" component.

Under this assumption, the likelihood of a particular set of observations $\left\{y_{j}\right\}$ given that the actual parameter vector is $\overline{\mathbf{x}}$ is given by:

$$
p(\overline{\mathbf{y}} ; \overline{\mathbf{x}}, \sigma)=\prod_{j=1}^{m} g_{\sigma}\left(\epsilon_{j}\right)
$$

## Least Squares Fitting: Background — Statistics (Handwaving)

Since the observations $\left\{y_{j}\right\}$ are known, the most likely value of $\overline{\mathrm{x}}$ is obtained by maximizing $p(\overline{\mathbf{y}} ; \overline{\mathbf{x}}, \sigma)$ with respect to $\overline{\mathbf{x}}$. The resulting value $\overline{\mathrm{x}}^{*}$ is called the maximum likelihood estimate of the parameters.

When the discrepancies are assumed to be normally distributed, we have

$$
g_{\sigma}(\bar{\epsilon})=\frac{1}{\sqrt{2 \pi \sigma^{2}}} \exp \left(-\frac{\epsilon^{2}}{2 \sigma^{2}}\right)
$$

so that

$$
p(\overline{\mathbf{y}} ; \overline{\mathbf{x}}, \sigma)=\left[2 \pi \sigma^{2}\right]^{-m / 2} \exp \left(-\frac{1}{2} \sum_{j=1}^{m} \frac{\left[y_{j}-\Phi\left(\overline{\mathbf{x}} ; t_{j}\right)\right]^{2}}{\sigma^{2}}\right)
$$

It is clear that $p(\overline{\mathbf{y}} ; \overline{\mathbf{x}}, \sigma)$ is maximized when the sum-of-squares $\sum_{j=1}^{m}\left[y_{j}-\Phi\left(\overline{\mathrm{x}} ; t_{j}\right)\right]^{2}$ is minimized.

## Least Squares Fitting: Background — Statistics (Handwaving) 3 of 3

Close your eyes if you are a real statistician!

## Summary (Statistical motivation)

When the discrepancies are assumed to be independent, identically distributed with a normal distribution function, the maximum likelihood estimate is obtained by minimizing the sum of the squares.

These assumptions on $\left\{\epsilon_{j}\right\}$ are very common, but do not describe the only situation for which the minimizer of the sum-of-squares makes statistical sense.

Disclaimer: With apologies to all real statisticians out there...

## Special Case: Linear Least Squares

When each function $r_{j}(\overline{\mathbf{x}})$ is linear, the Jacobian $J$ is constant, and we have

$$
f(\overline{\mathbf{x}})=\frac{1}{2}\left\|J \overline{\mathbf{x}}+\overline{\mathbf{r}}_{0}\right\|_{2}^{2}, \quad \overline{\mathbf{r}}_{0}=\overline{\mathbf{r}}(0) .
$$

the gradient and Hessian are also simple expressions

$$
\nabla f(\overline{\mathbf{x}})=J^{T}\left(J \overline{\mathbf{x}}+\overline{\mathbf{r}}_{0}\right), \quad \nabla^{2} f(\overline{\mathbf{x}})=J^{T} J
$$

The objective is convex; solving for the stationary point $\nabla f\left(\overline{\mathbf{x}}^{*}\right)=0$ gives the system of equations

$$
J^{T} J \overline{\mathbf{x}^{*}}=-J^{T} \overline{\mathbf{r}}_{0},
$$

this system of equations is known as the normal equations.

## Special Case: Linear Least Squares

The linear least squares problem is of interest since many models used in practice $\Phi(\overline{\mathbf{x}} ; t)$ are linear.

The linear least squares problem is really a question of numerical linear algebra (Math 543, and Math 541), but given its importance it is worth taking a quick look at three algorithms for finding the solution.

We assume:

- $m \geq n$. (Over-Determined: More measurements than parameters)
- $J$ has full column rank.

The Cholesky factorization $R^{T} R=J^{\top} J$ (where $R$ is $n \times n$ upper triangular, and $J$ is $m \times n$ ) is guaranteed to exist when these assumptions are true.

## Special Case: Linear Least Squares

Approach \#1: Direct solution of the Normal Equations.

- Compute the coefficient matrix $J^{T} J$ and the right-hand-side $-J^{T} \overline{\mathbf{r}}_{0}$.
- Compute the Cholesky factorization $R^{T} R=\operatorname{cholesky}\left(J^{T} J\right)$ of the symmetric matrix $J^{\top} J$.
- Perform a forward and backward substitution with the Cholesky factors to recover the solution $\overline{\mathbf{x}}^{*}$.

This approach has one significant disadvantage. - The condition number of $J^{T} J$

$$
\operatorname{cond}\left(J^{T} J\right)=\frac{|\lambda|_{\max }\left(J^{T} J\right)}{|\lambda|_{\min }\left(J^{T} J\right)}=\operatorname{cond}(J)^{2}=\left[\frac{\sigma_{\max }(J)}{\sigma_{\min }(J)}\right]^{2}
$$

is the square of the condition number of $J$.

## Special Case: Linear Least Squares

The relative error of the computed solution is (usually) proportional to the condition number, the fact that $\operatorname{cond}\left(J^{T} J\right)=\operatorname{cond}(J)^{2}$ is very bad news indeed when $J$ is ill-conditioned.
Note: $J^{T} J$ is essentially a Hilbert matrix.
In the worst case scenario, the Cholesky factorization may break down due to roundoff errors when when $J$ is ill-conditioned!

Approach \#2: QR-factorization of $J-J \Pi=Q R$, where $Q$ is orthonormal, and $R$ upper triangular

Since the Euclidean norm is invariant under orthogonal transformations, we have

$$
\left\|J \overline{\mathrm{x}}+\overline{\mathbf{r}}_{0}\right\|_{2}=\left\|U\left(J \overline{\mathrm{x}}+\overline{\mathbf{r}}_{0}\right)\right\|_{2}
$$

for any $m \times m$ orthogonal matrix U .

## Special Case: Linear Least Squares

Suppose we perform (Math 543) a QR-factorization with column pivoting on the matrix $J$ to obtain

$$
\mathbf{J} \boldsymbol{\Pi}=\mathbf{Q}\left[\begin{array}{c}
R \\
0
\end{array}\right]=\left[\begin{array}{ll}
Q_{1} & Q_{2}
\end{array}\right]\left[\begin{array}{c}
R \\
0
\end{array}\right]=\mathbf{Q}_{\mathbf{1}} \mathbf{R}_{\mathbf{1}}
$$

where
$\Pi \quad$ is an $n \times n$ permutation matrix ( $\Rightarrow$ orthogonal)
$Q \quad$ is $m \times m$ orthogonal
$Q_{1}$ is the first $n$ columns of $Q$.
$Q_{2} \quad$ is the remaining $(m-n)$ columns of $Q$.
$R \quad$ is $n \times n$ upper triangular

## Special Case: Linear Least Squares

This gives us

$$
\begin{aligned}
\left\|J \overline{\mathbf{x}}+\overline{\mathbf{r}}_{0}\right\|_{2}^{2} & =\left\|\left[\begin{array}{c}
Q_{1}^{T} \\
Q_{2}^{T}
\end{array}\right]\left(J \Pi \Pi^{T} \overline{\mathbf{x}}+\overline{\mathbf{r}}_{0}\right)\right\|_{2}^{2} \\
& =\left\|\left[\begin{array}{c}
R \\
0
\end{array}\right]\left(\Pi^{T} \overline{\mathbf{x}}\right)+\left[\begin{array}{c}
Q_{1}^{T} \overline{\mathbf{r}}_{0} \\
Q_{2}^{T} \overline{\mathbf{r}}_{0}
\end{array}\right]\right\|_{2}^{2} \\
& =\left\|\mathbf{R}\left(\Pi^{\top} \overline{\mathbf{x}}\right)+\mathbf{Q}_{1}^{T} \overline{\mathbf{r}}_{0}\right\|_{2}^{2}+\left\|\mathbf{Q}_{2}^{\top} \overline{\mathbf{r}}_{0}\right\|_{2}^{2}
\end{aligned}
$$

The second part is unaffected by $\overline{\mathbf{x}}$, but setting the first term to zero minimizes $\left\|J \overline{\mathrm{x}}+\overline{\mathbf{r}}_{0}\right\|_{2}^{2}$, i.e. we find

$$
\overline{\mathbf{x}}^{*}=-\boldsymbol{\Pi} \mathbf{R}^{-1} \mathbf{Q}_{1}^{\top} \overline{\mathbf{r}}_{0}
$$

In practice, $R \overline{\mathbf{z}}=-Q_{1}^{T} \overline{\mathbf{r}}_{0}$ is solved by backward substitution, and then $\overline{\mathbf{x}}^{*}=\Pi \overline{\mathbf{z}}$.

## Special Case: Linear Least Squares

The QR-based approach does not square the condition number of $J$. The relative error of the solution will be proportional to a value in the range $\left[\operatorname{cond}(J)\right.$, cond $\left.(J)^{2}\right]$, usually $\ll \operatorname{cond}(J)^{2}$, rather than cond $(J)^{2}$ for the direct solution of the normal equations.

In most situations, the QR-based approach is the way to go.
However, if/when we require maximal robustness and/or want to extract more information about the sensitivity of the solution to errors in $J$ or $\mathbf{r}_{0}$ we can bring out the big hammer -

## Approach \#3: Singular Value Decomposition (SVD) of $J$.

The SVD [mathematics] is known by many names: the Proper Orthogonal Decomposition (POD), the Karhunen-Loève (KL-) Decomposition [signal analysis], Principal Component Analysis (PCA) [statistics], Empirical Orthogonal Functions, etc...

## Special Case: Linear Least Squares

The SVD of $J$ is given by (Math 543)

$$
J=U\left[\begin{array}{l}
S \\
0
\end{array}\right] V^{T}=\left[\begin{array}{ll}
U_{1} & U_{2}
\end{array}\right]\left[\begin{array}{l}
S \\
0
\end{array}\right] V^{T}=\mathrm{U}_{1} \mathrm{SV}^{\top}
$$

where
$U \quad$ is $m \times m$ orthogonal
$U_{1}$ contains the first $n$ columns of $U$
$U_{2}$ contains the remaining $(m-n)$ columns of $U$
$V$ is $n \times n$ orthogonal
$S \quad$ is $n \times n$ diagonal, with elements $\sigma_{1} \geq \sigma_{2} \geq \cdots \geq \sigma_{n}>0$.
Note that $J^{T} J=V S^{2} V^{T}$, so that the columns of $V$ are eigenvectors of $J^{\top} J$ with eigenvalues $\sigma_{j}^{2}$.

## Special Case: Linear Least Squares

Now,

$$
\begin{aligned}
\left\|J \overline{\mathbf{x}}+\overline{\mathbf{r}}_{0}\right\|_{2}^{2} & =\left\|\left[\begin{array}{l}
S \\
0
\end{array}\right]\left(V^{T} \overline{\mathbf{x}}\right)+\left[\begin{array}{c}
U_{1}^{T} \\
U_{2}^{T}
\end{array}\right] \overline{\mathbf{r}}_{0}\right\|_{2}^{2} \\
& =\left\|\mathbf{S}\left(\mathbf{V}^{\top} \overline{\mathbf{x}}\right)+\mathbf{U}_{1}^{\top} \overline{\mathbf{r}}_{0}\right\|_{2}^{2}+\left\|\mathbf{U}_{2}^{\top} \overline{\mathbf{r}}_{0}\right\|^{2}
\end{aligned}
$$

Again, we find the optimum by setting the first contribution to zero, i.e.

$$
\overline{\mathbf{x}}^{*}=V S^{-1} U_{1}^{T} \overline{\mathbf{r}}_{0}=\sum_{i=1}^{n} \frac{\overline{\mathbf{u}}_{i}^{T} \overline{\mathbf{r}}_{0}}{\sigma_{i}} \overline{\mathbf{v}}_{i}
$$

where $\overline{\mathbf{u}}_{i}$ and $\overline{\mathbf{v}}_{i}$ are the $i$ th columns of $U$ and $V$, respectively.

## Special Case: Linear Least Squares

The expression for the optimum,

$$
\overline{\mathbf{x}}^{*}=\sum_{i=1}^{n} \frac{\overline{\mathbf{u}}_{i}^{T} \overline{\mathbf{r}}_{0}}{\sigma_{i}} \overline{\mathbf{v}}_{i}
$$

gives us information about the sensitivity of $\overline{\mathbf{x}}^{*}$. When $\sigma_{i}$ is small, $\overline{\mathbf{x}}^{*}$ is particularly sensitive to perturbations that affect $\overline{\mathbf{u}}_{i}^{T} \overline{\mathbf{r}}_{0}$.

This information is useful when $\sigma_{n} / \sigma_{1} \ll 1$ ( $J$ nearly rank-deficient).

## Special Case: Linear Least Squares

Summary: Three Methods for $J^{\top} J \overline{\mathbf{x}}^{*}=-J^{\top} \overline{\mathbf{r}}_{0}$.
All three approaches are useful under the right circumstances

- Cholesky-based algorithm is particularly useful when $m \gg n$, in this case it is practical to store $J^{\top} J$, but not $J$. When $J$ is rank-deficient or ill-conditioned diagonal pivoting must be implemented to limit the propagation of round-off errors. (This approach to be used sparingly)
- In the QR-approach with column pivoting, ill-conditioning usually causes the elements in the lower right-hand corner of the matrix $R$ to be much smaller than the other elements. The strategy produces a solution to a nearby problem in which $J$ is slightly perturbed. (This is the preferred every-day approach)

## Special Case: Linear Least Squares

- The SVD-approach is the most robust and reliable for illconditioned problems. When $J$ is actually rank deficient, some of the singular values $\sigma_{i}$ are exactly zero. Any vector of the form

$$
\overline{\mathbf{x}}^{*}=\sum_{\left.i: * \sigma_{i} \neq 0\right)} \frac{\overline{\mathbf{u}}_{i}^{T} \overline{\mathbf{r}}_{0}}{\sigma_{i}}+\sum_{i:\left(\sigma_{i}=0\right)} \tau_{i} \overline{\mathbf{v}}_{i}
$$

(for any values $\tau_{i}$ ) is a minimizer of the least-squares problem. Usually the minimum-norm $\left(\tau_{i}=0\right)$ solution is desirable. (When $J$ is rank-deficient, this is the only approach of the three that works)

With these results in our tool-box, we are ready to attack the solution of the non-linear least squares problem next time.
