Summary Orthogonal Distance Regression Linear Least Squares Nonlinear Least Squares

Summary: Linear Least Squares

Our study of non-linear least squares problems started with a look at **linear least squares**, where each residual  $r_j(\bar{\mathbf{x}})$  is linear, and the Jacobian therefore is constant. The objective of interest is

$$f(\overline{\mathbf{x}}) = \frac{1}{2} \|J\overline{\mathbf{x}} + \overline{\mathbf{r}}_0\|_2^2, \quad \overline{\mathbf{r}}_0 = \overline{\mathbf{r}}(0),$$

solving for the stationary point  $\nabla f(\bar{\mathbf{x}}^*) = 0$  gives the **normal equations** 

$$J^T J \overline{\mathbf{x}^*} = -J^T \overline{\mathbf{r}}_0$$
.

We have three approaches to solving the normal equations for  $\bar{\mathbf{x}}^*$  — in increasing order of **computational complexity** and **stability**:

- (i) Cholesky factorization of  $J^T J$ ,
- (ii) QR-factorization of J, and
- (iii) Singular Value Decomposition of J.

Problem: Nonlinear Least Squares

$$ar{\mathbf{x}}^* = \operatorname*{arg\;min}_{ar{\mathbf{x}} \in \mathbb{R}^n} \left[ f(ar{\mathbf{x}}) \right] = \operatorname*{arg\;min}_{ar{\mathbf{x}} \in \mathbb{R}^n} \left[ \frac{1}{2} \sum_{j=1}^m r_j(ar{\mathbf{x}})^2 \right], \quad m \geq n,$$

where the **residuals**  $r_j(\bar{\mathbf{x}})$  are of the form  $r_j(\bar{\mathbf{x}}) = y_j - \Phi(\bar{\mathbf{x}}; t_j)$ . Here,  $y_j$  are the **measurements** taken at the **locations/times**  $t_j$ , and  $\Phi(\bar{\mathbf{x}}; t_j)$  is our **model**.

The key approximation for the Hessian

$$\nabla^{2}\mathbf{f}(\bar{\mathbf{x}}) = J(\bar{\mathbf{x}})^{\mathsf{T}}J(\bar{\mathbf{x}}) + \sum_{j=1}^{m} r_{j}(\bar{\mathbf{x}})\nabla^{2}r_{j}(\bar{\mathbf{x}}) \approx \mathbf{J}(\bar{\mathbf{x}})^{\mathsf{T}}\mathbf{J}(\bar{\mathbf{x}}).$$

## **Hybrid Algorithms:**

- When implementing Gauss-Newton or Levenberg-Marquardt, we should implement a safe-guard for the large residual case, where the Hessian approximation fails.
- If, after some reasonable number of iterations, we realize that
  the residuals are **not** going to zero, then we are better off
  switching to a general-purpose algorithm for non-linear optimization, such as a quasi-Newton (BFGS), or Newton method.

**Trust-region algorithm: Levenberg-Marquardt**, with the subproblem:

$$\bar{\mathbf{p}}_k^{\text{LM}} = \operatorname*{arg\,min}_{\bar{\mathbf{p}} \in \mathbb{R}^n} \frac{1}{2} \|J(\bar{\mathbf{x}}_k)\bar{\mathbf{p}} + \bar{\mathbf{r}}_k\|_2^2, \quad \text{subject to } \|\bar{\mathbf{p}}\| \leq \Delta_k.$$

Slight advantage over Gauss-Newton (global convergence), same local convergence properties; also (locally) equivalent to a linear least squares problem.

Summary Orthogonal Distance Regression

Error Models
Weighted Least Squares / Orthogonal Distance Regression
ODR = Nonlinear Least Squares, Exploiting Structure

Fixed Regressor Models vs. Errors-In-Variables Models

So far we have assumed that there are **no errors** in the variables describing **where** / **when** the measurements are made, *i.e.* in the data set  $\{t_j, y_j\}$  where  $t_j$  denote times of measurement, and  $y_j$  the measured value, we have assumed that  $t_j$  are **exact**, and the measurement errors are in  $y_j$ .

Under this assumption, the discrepancies between the model and the measured data are

$$\epsilon_i = y_i - \Phi(\bar{\mathbf{x}}; t_i), \quad i = 1, 2, \dots, m.$$

Next, we will take a look at the situation where we take errors in  $t_j$  into account — these models are known as **errors-in-variables models**, and their solutions in the linear case are referred to as **total least squares optimization**, or in the non-linear case as **orthogonal distance regression**.

Weighted Least Squares / Orthogonal Distance Regression

ODR = Nonlinear Least Squares, Exploiting Structure

Least Squares vs. Orthogonal Distance Regression

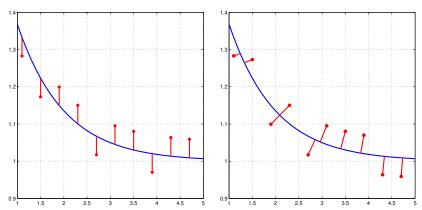

Figure: (left) An illustration of how the error is measured in standard (fixed regressor) least squares optimization. (right) An example of orthogonal distance regression, where we measure the shortest distance to the model curve. [The right figure is actually not correct, why?]

Peter Blomgren, (blomgren.peter@gmail.com)

Orthogonal Distance Regression

-(9/22)

Summary Orthogonal Distance Regression Error Models Weighted Least Squares / Orthogonal Distance Regression ODR = Nonlinear Least Squares, Exploiting Structure

Orthogonal Distance Regression: The Weights

The weight-vectors  $\mathbf{d}$  and  $\mathbf{w}$  must either be supplied by the modeler, or estimated in some clever way.

If all the weights are the same  $w_i = d_i = \mathcal{C}$ , then each term in the sum is simply the shortest distance between the point  $(t_i, y_i)$  and curve  $\Phi(\bar{\mathbf{x}}; t)$  (as illustrated in the previous figure).

In order to get the orthogonal-looking figure, I set  $w_i =$ 1/0.5 and  $d_i = 1/4$ , thus adjusting for the different scales in the t- and y-directions.

The shortest path between the point and the curve will be normal (orthogonal) to the curve at the point of intersection.

We can think of the scaling (weighting) as adjusting for measuring time in fortnights, seconds, milli-seconds, micro-seconds, or nano-seconds...

**— (11/22)** 

Orthogonal Distance Regression

Weighted Least Squares / Orthogonal Distance Regression ODR = Nonlinear Least Squares, Exploiting Structure

Orthogonal Distance Regression

For the mathematical formulation of orthogonal distance regression we introduce perturbations (errors)  $\delta_i$  for the variables  $t_i$ , in addition to the errors  $\epsilon_i$  for the  $y_i$ 's.

We relate the measurements and the model in the following way

$$\epsilon_j = y_j - \Phi(\bar{\mathbf{x}}; t_j + \delta_j),$$

and define the minimization problem:

$$(\overline{\mathbf{x}}^*, \overline{\delta}^*) = \operatorname*{arg\,min}_{\overline{\mathbf{x}}, \overline{\delta}} \frac{1}{2} \sum_{\mathbf{j} = 1}^{\mathbf{m}} \left[ \mathbf{w}_{\mathbf{j}}^2 \bigg[ \mathbf{y}_{\mathbf{j}} - \boldsymbol{\Phi}(\overline{\mathbf{x}}; \ \mathbf{t}_{\mathbf{j}} + \delta_{\mathbf{j}}) \bigg]^2 + \mathbf{d}_{\mathbf{j}}^2 \delta_{\mathbf{j}}^2 \bigg],$$

where  $\mathbf{d}$  and  $\mathbf{w}$  are two vectors of weights which denote the relative significance of the error terms.

Peter Blomgren, (blomgren.peter@gmail.com)

Orthogonal Distance Regression

**— (10/22)** 

Summary Orthogonal Distance Regression Weighted Least Squares / Orthogonal Distance Regression = Nonlinear Least Squares, Exploiting Structure

Orthogonal Distance Regression: In Terms of Residuals r<sub>i</sub>

By identifying the 2m residuals

$$r_{j}(\overline{\mathbf{x}}, \overline{\delta}) = \begin{cases} w_{j} \left[ y_{j} - \Phi(\overline{\mathbf{x}}; \ t_{j} + \delta_{j}) \right] & j = 1, 2, \dots, m \\ d_{j-m}\delta_{j-m} & j = (m+1), (m+2), \dots, 2m \end{cases}$$

we can rewrite the optimization problem

$$(\mathbf{\bar{x}}^*, \mathbf{\bar{\delta}}^*) = \operatorname*{arg\,min} rac{1}{2} \sum_{j=1}^m w_j^2 igg[ y_j - \Phi(\mathbf{\bar{x}}; \ t_j + \delta_j) igg]^2 + d_j^2 \delta_j^2,$$

in terms of the 2*m*-vector  $\overline{\mathbf{r}}(\overline{\mathbf{x}}, \overline{\delta})$ 

$$(\bar{\mathbf{x}}^*, \bar{\delta}^*) = \mathop{\arg\min}_{\bar{\mathbf{x}}, \bar{\delta}} \frac{1}{2} \sum_{i=1}^{2m} \mathsf{r_j}(\bar{\mathbf{x}}, \bar{\delta})^2 = \mathop{\arg\min}_{\bar{\mathbf{x}}, \bar{\delta}} \frac{1}{2} \|\mathsf{r}(\bar{\mathbf{x}}, \bar{\delta})\|_2^2.$$

Orthogonal Distance Regression  $\rightarrow$  Least Squares

If we take a cold hard stare at the expression

$$(\bar{\mathbf{x}}^*, \bar{\delta}^*) = \operatorname*{arg\,min}_{\bar{\mathbf{x}}, \bar{\delta}} \frac{1}{2} \sum_{i=1}^{2m} r_j(\bar{\mathbf{x}}, \bar{\delta})^2 = \operatorname*{arg\,min}_{\bar{\mathbf{x}}, \bar{\delta}} \frac{1}{2} \|\bar{\mathbf{r}}(\bar{\mathbf{x}}, \bar{\delta})\|_2^2.$$

We realize that this is now a standard (nonlinear) least squares problem with 2m residuals and (n+m) unknowns —  $\{\bar{\mathbf{x}}, \bar{\delta}\}$ .

We can use any of the techniques we have previously explored for the solution of the nonlinear least squares problem.

However, a straight-forward implementation of these strategies may prove to be quite expensive, since the number of parameters have doubled to 2m and the number of independent variables have grown from n to (n+m). Recall that usually  $m\gg n$ , so this is a drastic growth of the problem.

Orthogonal Distance Regression

Summary Orthogonal Distance Regression

Error Models
Weighted Least Squares / Orthogonal Distance Regression
ODR = Nonlinear Least Squares, Exploiting Structure

 $\mathsf{ODR} \to \mathsf{Least}\ \mathsf{Squares}$ : Exploiting Structure

Fortunately we can save a lot of work by exploiting the structure of the Jacobian of the Least Squares problem originating from the orthogonal distance regression — many entries are zero!

$$\frac{\partial r_{j}}{\partial \delta_{i}} = w_{j} \frac{\partial [y_{j} - \Phi(\bar{\mathbf{x}}; t_{j} + \delta_{j})]}{\partial \delta_{i}} = 0, \quad \forall i, j \leq m, i \neq j$$

$$\frac{\partial r_{j}}{\partial \delta_{i}} = \frac{\partial [d_{j-m}\delta_{j-m}]}{\partial \delta_{i}} = \begin{cases} 0 & i \neq (j-m), j > m \\ d_{j-m} & i = (j-m), j > m \end{cases}$$

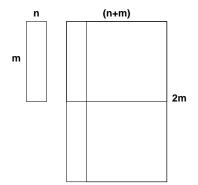

$$\frac{\partial r_{j}}{\partial x_{i}} = \frac{\partial [d_{j-m}\delta_{j-m}]}{\partial x_{i}} = 0, \quad i = 1, 2, \dots, n, \quad j > m$$

Let  $v_j = w_j \frac{\partial [y_j - \Phi(\bar{\mathbf{x}}; t_j + \delta_j)]}{\partial \delta_j}$ , and let  $D = \operatorname{diag}(\bar{\mathbf{d}})$ , and  $V = \operatorname{diag}(\bar{\mathbf{v}})$ , then we can write the Jacobian of the residual function in matrix form...

**— (15/22)** 

Orthogonal Distance Regression  $\rightarrow$  Least Squares: Problem Size

**Figure:** We recast ODR as a much larger standard nonlinear least squares problem.

Standard LSQ-solution via QR/SVD  $\sim \mathcal{O}(mn^2)$ , for  $m \gg n$ ; slows down by a factor of  $2(1 + m/n)^2$ .

(14/22)

Summary Orthogonal Distance Regression

Error Models
Weighted Least Squares / Orthogonal Distance Regression
ODR = Nonlinear Least Squares, Exploiting Structure

 $\mathsf{ODR} \to \mathsf{Least}\ \mathsf{Squares}$ : The Jacobian

We now have

$$J(\overline{\mathbf{x}}, \overline{\delta}) = \begin{bmatrix} \widehat{J} & V \\ \hline 0 & D \end{bmatrix},$$

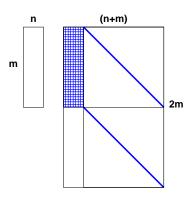

where D and V are  $m \times m$  diagonal matrices,  $D = \operatorname{diag}(\mathbf{\bar{d}})$ , and  $V = \operatorname{diag}(\mathbf{\bar{v}})$ , and  $\widehat{J}$  is the  $m \times n$  matrix defined by

$$\widehat{J} = \left[\frac{\partial [w_j(y_j - \Phi(\overline{\mathbf{x}}; t_j + \delta_j))]}{\partial x_i}\right]_{\substack{j=1,2,\ldots,m\\j=1,2,\ldots,n}}^{j=1,2,\ldots,m}$$

We can now use this matrix in *e.g.* the Levenberg-Marquardt algorithm...

 $\mathsf{ODR} \to \mathsf{Least}\ \mathsf{Squares}$ : The Jacobian — Structure

**Figure:** If we exploit the structure of the Jacobian, the problem is still somewhat tractable.

Summary Orthogonal Distance Regression Error Models
Weighted Least Squares / Orthogonal Distance Regression
ODR = Nonlinear Least Squares, Exploiting Structure

 $\mathsf{ODR} \to \mathsf{Least}\ \mathsf{Squares} \to \mathsf{Levenberg}\text{-}\mathsf{Marquardt}$ 

2 of 2

$$\left[\begin{array}{c|c}
\widehat{J}^{T}\widehat{J} + \lambda I_{n} & \widehat{J}^{T}V \\
\hline
V\widehat{J} & V^{2} + D^{2} + \lambda I_{m}
\end{array}\right] \left[\begin{array}{c|c}
\overline{\mathbf{p}}_{x} \\
\overline{\mathbf{p}}_{\delta}
\end{array}\right] = -\left[\begin{array}{c|c}
\widehat{J}^{T}\widetilde{\mathbf{r}}_{1} \\
\hline
V\widetilde{\mathbf{r}}_{1} + D\widetilde{\mathbf{r}}_{2}
\end{array}\right]$$

$$\bar{\mathbf{p}}_{\delta} = -\left[V^2 + D^2 + \lambda I_m\right]^{-1} \left[\left(V\tilde{\mathbf{r}}_1 + D\tilde{\mathbf{r}}_2\right) + V\widehat{J}\bar{\mathbf{p}}_{x}\right]$$

This leads to the  $n \times n$ -system  $A\bar{\mathbf{p}}_x = \bar{\mathbf{b}}$ , where

$$A = \left[ \widehat{J}^T \widehat{J} + \lambda I_n - \widehat{J}^T V \left[ V^2 + D^2 + \lambda I_m \right]^{-1} V \widehat{J} \right]$$

$$\mathbf{\bar{b}} = \left[ -\widehat{J}^T \mathbf{\tilde{r}}_1 + \widehat{J}^T V \left[ V^2 + D^2 + \lambda I_m \right]^{-1} \left[ V \mathbf{\tilde{r}}_1 + D \mathbf{\tilde{r}}_2 \right] \right].$$

Hence, the total cost of finding the LM-step is only marginally more expensive than for the standard least squares problem.

**— (19/22)** 

 $\mathsf{ODR} \to \mathsf{Least}\ \mathsf{Squares} \to \mathsf{Levenberg}\text{-}\mathsf{Marquardt}$ 

1 of 2

If we partition the step vector  $\mathbf{\bar{p}}$ , and the residual vector  $\mathbf{\bar{r}}$  into

$$oldsymbol{ar{p}} = \left[egin{array}{c} oldsymbol{ar{p}}_{ar{N}} \ oldsymbol{ar{p}}_{\delta} \end{array}
ight], \quad oldsymbol{ar{r}} = \left[egin{array}{c} oldsymbol{ ilde{r}}_1 \ oldsymbol{ ilde{r}}_2 \end{array}
ight]$$

where  $\bar{\mathbf{p}}_x \in \mathbb{R}^n$ ,  $\bar{\mathbf{p}}_\delta \in \mathbb{R}^m$ , and  $\tilde{\mathbf{r}}_1, \tilde{\mathbf{r}}_2 \in \mathbb{R}^m$ , then *e.g.* we can write the Levenberg-Marquardt subproblem in partitioned form

$$\begin{bmatrix}
\widehat{J}^{T}\widehat{J} + \lambda I_{n} & \widehat{J}^{T}V \\
V\widehat{J} & V^{2} + D^{2} + \lambda I_{m}
\end{bmatrix}
\begin{bmatrix}
\overline{\mathbf{p}}_{x} \\
\overline{\mathbf{p}}_{\delta}
\end{bmatrix} = -\begin{bmatrix}
\widehat{J}^{T}\widetilde{\mathbf{r}}_{1} \\
V\widetilde{\mathbf{r}}_{1} + D\widetilde{\mathbf{r}}_{2}
\end{bmatrix}$$

Since the (2,2)-block  $V^2 + D^2 + \lambda I_m$  is diagonal, we can eliminate the  $\bar{\mathbf{p}}_{\delta}$  variables from the system...

Orthogonal Distance Regression

**— (18/22)** 

Summary Orthogonal Distance Regression Error Models
Weighted Least Squares / Orthogonal Distance Regression
ODR = Nonlinear Least Squares, Exploiting Structure

 $\mathsf{ODR} \to \mathsf{LSQ}\ (2m \times (n+m)) \to \mathsf{Levenberg\text{-}Marquardt} \to \mathsf{LSQ}\ (m \times n)$ 

The derived system is typically very ill-conditioned since we have formed a modified version of the normal equations  $\widehat{J}^T\widehat{J}+$  "stuff"... With some work we can recast is as an  $m\times n$  linear least squares problem  $\bar{\mathbf{p}}_{\mathrm{x}}=\arg\min_{\bar{\mathbf{p}}}\|\widetilde{A}\bar{\mathbf{p}}-\tilde{\mathbf{b}}\|_2$ , where

$$\tilde{A} = \left[\hat{J} + \lambda [\hat{J}^T]^{\dagger} - V \left[V^2 + D^2 + \lambda I_m\right]^{-1} V \hat{J}\right]$$

$$\tilde{\mathbf{b}} = \left[ -\tilde{\mathbf{r}}_1 + V \left[ V^2 + D^2 + \lambda I_m \right]^{-1} \left[ V\tilde{\mathbf{r}}_1 + D\tilde{\mathbf{r}}_2 \right] \right]$$

Where the "mystery factor"  $[\widehat{J}^T]^{\dagger}$  is the **pseudo-inverse** of  $\widehat{J}^T$ . Expressed in terms of the QR-factorization  $QR = \widehat{J}$ , we have

$$\widehat{J}^T = R^T Q^T, \quad [\widehat{J}^T]^{\dagger} = QR^{-T},$$

Since  $QR^{-T}R^{T}Q^{T} = I = R^{T}Q^{T}QR^{-T}$ .
